## Abstract

The first-cycle behavior of layered Li-rich oxides, including  $\text{Li}_2\text{MnO}_3$  activation and cathode electrolyte interphase (CEI) formation, significantly influences their electrochemical performance. However, the  $\text{Li}_2\text{MnO}_3$  activation pathway and the CEI formation process are still controversial. Here, the first-cycle properties of  $x\text{Li}_2\text{MnO}_3 \cdot (1-x) \text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  ( $x = 0, 0.5, 1$ ) cathode materials were studied with an in-situ electrochemical quartz crystal microbalance (EQCM). The results demonstrate that a synergistic effect between layered  $\text{Li}_2\text{MnO}_3$  and  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  structures can significantly affect the activation pathway of  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ , leading to an extra-high capacity. It is demonstrated that  $\text{Li}_2\text{MnO}_3$  activation in Li-rich materials is dominated by electrochemical decomposition (oxygen redox), which is different from the activation process of pure  $\text{Li}_2\text{MnO}_3$  governed by chemical decomposition ( $\text{Li}_2\text{O}$  evolution). CEI evolution is closely related to  $\text{Li}^+$  extraction/insertion. The valence state variation of the metal ions (Ni, Co, Mn) in Li-rich material can promote CEI formation. This study is of significance for understanding and designing Li-rich cathode-based batteries.

**Key words:** Li-rich materials,  $\text{Li}_2\text{MnO}_3$  activation, oxygen redox, CEI evolution, in-situ EQCM

## 1. Introduction

Continuing interest in sustainable use of Li-ion batteries (LIBs) for electrical transportation is driving further developments in cathode materials. Layered Li-rich oxide cathode materials exhibit high specific capacity of more than 250 mAh g<sup>-1</sup> and thus are considered as potential candidates for the next-generation LIBs.<sup>1-2</sup> Nevertheless, commercial applications of Li-rich cathode materials are hindered by three main drawbacks. First, a large irreversible capacity loss happens in the first charge-discharge process. Second, their cyclability and rate capability are not sufficient. Third, significant voltage decay occurs during cycling.<sup>3-5</sup> All these issues are highly related to the first-cycle charge-discharge processes. Therefore, a better understanding and further controlling of the first-cycle processes of the Li-rich oxide cathode will be beneficial to improve its electrochemical properties.

Li<sub>2</sub>MnO<sub>3</sub> activation and cathode electrolyte interphases (CEI) formation/dissolution are two key reactions of Li-rich oxides in the first cycle. Many previous studies have been done to understand the activation process of Li<sub>2</sub>MnO<sub>3</sub> and CEI evolution. However, there is no consensus on the Li<sub>2</sub>MnO<sub>3</sub> activation process.<sup>6-11</sup> For example, it was claimed that O<sup>2-</sup> was oxidized to an O<sub>2</sub><sup>2-</sup> species or O<sub>2</sub><sup>2-</sup>-like localized electron holes on oxygen (“oxygen redox”) during Li<sub>2</sub>MO<sub>3</sub> (M = Ru, Sn, Mn) activation.<sup>6-9</sup> In contrast, other studies show very different Li<sub>2</sub>O evolution processes.<sup>10-11</sup> So far, most results were achieved using ex-situ electron paramagnetic resonance (EPR), X-ray photoelectron spectroscopy (XPS),<sup>6</sup> resonant inelastic X-ray scattering (RIXS),<sup>7</sup> in-situ Raman,<sup>9-10</sup> and wavelength dispersive spectroscopy (WDS)<sup>11</sup>. However, an important limitation of these experimental studies is that only surface information can be obtained.<sup>6-7,9-11</sup>

Electrochemical quartz crystal microbalance (EQCM) is able to detect in real time the mass change of a bulk electrode with high sensitivity during electrochemical processes.<sup>12-14</sup> For example, EQCM was used as a gravimetric probe to detect concentration and compositional changes of microporous activated carbons.<sup>12</sup> EQCM was also adapted to analyze formation of electrode/electrolyte interphase on graphite and Sn thin film electrodes.<sup>15,23</sup> CEI formation on the Li-rich  $0.5\text{Li}_2\text{MnO}_3 \cdot 0.5\text{LiMn}_{0.375}\text{Ni}_{0.375}\text{Co}_{0.25}\text{O}_2$  surface was also studied by EQCM, but the relationship between reaction in Li-rich electrodes and CEI formation was not clarified.<sup>25</sup>

There are two different activation pathways that can lead to mass loss of Li-rich cathode materials, namely electrochemical decomposition (oxygen redox)<sup>6-9</sup> and chemical decomposition ( $\text{Li}_2\text{O}$  evolution)<sup>10-11</sup>. The mass loss can be used as a criterion to differentiate the decomposition processes because electrochemical decomposition leads to  $\text{Li}^+$  de-intercalation from electrode while no  $\text{Li}^+$  de-intercalation occurs during chemical decomposition. In this study, we applied in-situ EQCM to investigate the first-cycle charge-discharge processes of  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  ( $0.5\text{Li}_2\text{MnO}_3 \cdot 0.5\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$ ),  $\text{Li}_2\text{MnO}_3$  and  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  electrode materials. We found that the activation pathway of  $\text{Li}_2\text{MnO}_3$  in  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  is influenced by synergistic effects between  $\text{Li}_2\text{MnO}_3$  and  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$ . Our results show that the  $\text{Li}_2\text{MnO}_3$  activation in Li-rich material is dominated by electrochemical decomposition (oxygen redox), as opposed to activation of pure  $\text{Li}_2\text{MnO}_3$ , which is governed by chemical decomposition ( $\text{Li}_2\text{O}$  evolution). CEI formation is evidently affected by changes in the valence states of metal ions in Li-rich material. Our study has deepened the understanding of the first-cycle behavior of Li-rich materials, which will be helpful for designing Li-rich cathode-based batteries.

## 2. Experimental

### 2.1. Materials Preparation and Characterization

A modified Pechini method was adopted to prepare  $\text{Li}_2\text{MnO}_3$ ,  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  and  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  materials, as reported in our previous study.<sup>16</sup> Citric acid, dissolved in ethylene glycol in a 1:4 molar ratio, was used as chelating agent. Then a metal ion solution containing a stoichiometric amount of  $\text{Li}(\text{CH}_3\text{COO})\cdot\text{H}_2\text{O}$  (an excess of 5% in molar ratio),  $\text{Ni}(\text{CH}_3\text{COO})_2\cdot 4\text{H}_2\text{O}$ ,  $\text{Mn}(\text{CH}_3\text{COO})_2\cdot 4\text{H}_2\text{O}$  and  $\text{Co}(\text{CH}_3\text{COO})_2\cdot 4\text{H}_2\text{O}$  was added dropwise. A clear solution was obtained after heating at 90 °C while stirring for 1 h. The resulting solution was further heated at 140 °C to esterify and evaporate the excess water. The residue was vacuum dried in an oven at 180 °C for 12 h for thermal polymerization to yield an organic polymer foam. The obtained precursor was pre-heated at 450 °C for 6 h, and then calcined at 700 °C for 24 h.

The microstructure and crystal structure were characterized by scanning electron microscope (SEM, Hitachi S-4800) and powder X-ray diffraction (XRD, Philips X'Pert Pro), respectively. XRD measurements were run over the  $2\theta$  range of 15-90°. The scan rate was 1 °min<sup>-1</sup>. XRD refinement was conducted by Rietveld method using Topas program (Bruker, Topas 4.2).

### 2.2. EQCM Measurements

#### (1) Preparation of materials modified quartz crystal electrode

Slurry composed of 80 wt. % cathode materials, 10 wt. % acetylene black and 10 wt. % PVDF in N-methylpyrrolidone was prepared and dripped on the Au-coated AT-cut 7.995 MHz 1 inch diameter quartz crystal surface. Prior to use, the Au-coated crystal was rinsed with ethanol and

1 acetone for 10 min each, respectively. The loaded active material was controlled at  $4.5 \pm 0.5$   $\mu\text{g}$ .  
2 Under this mass load, the quartz crystal can maintain a resonance oscillation ( $\Delta f/f_0 < 2\%$ .  $\Delta f$  is  
3 the mass change of the load, and  $f_0$  is resonance frequency of Au crystal).<sup>17,23</sup> The mass of each  
4 material was obtained from the difference between the resonance frequency of the Au-coated crystal  
5 with and without active material. The geometric area of the Au electrode was  $0.196 \text{ cm}^2$ . The  
6 prepared quartz crystal was dried at  $80^\circ\text{C}$  for 12 h in vacuum. After cooling down, it was fixed on  
7 the crystal holder and used as the working electrode. Fig S1a and b shows an optical micrograph of a  
8  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  slurry-coated quartz crystal after drying at  $80^\circ\text{C}$  for 12 h in vacuum and an  
9 optical micrograph of the  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  slurry surface. The loaded material is distributed  
10 uniformly in the center of Au crystal.

## 11 (2) Details of measurements

12 EQCM measurements were conducted using a three-electrode system at  $25^\circ\text{C}$ . Fig 1 shows a  
13 schematic diagram of the EQCM setup. Both the reference and the counter electrode are lithium  
14 strips. The electrochemical cell assembly was operated in an argon-filled glove box at room  
15 temperature. 1 M  $\text{LiPF}_6$  (LP) dissolved in ethylene carbonate/dimethyl carbonate (EC: DMC = 1:1  
16 v/v) was used as the electrolyte. For each EQCM test, the volume of electrolyte was 0.8 mL.  
17 CV-EQCM tests were conducted by a CHI440C EQCM workstation (CH Instruments) and its  
18 accessories. For this equipment, a 1 Hz frequency increase means a 1.34 ng weight decrease. Before  
19 the CV-EQCM tests, the three-electrode system was kept standing for 6 h to reach steady state. CV  
20 curves were generated between 2.0 V to 4.8 V with a scanning rate of  $0.2 \text{ mV s}^{-1}$ . The mass change  
21 of the working electrodes was recorded by the EQCM during the CV measurements.

When  $\Delta f/f_0 < 2\%$ , the *mpe* (mass accumulated per mole of electron transferred) values were estimated according to the Sauerbrey equation (eq 1) and Faraday's law (eq 2),<sup>17,23</sup>

$$\Delta m = -\frac{A(\mu_q \rho_q)^{0.5} \Delta f}{2f_0^2} = -C_f \cdot \Delta f \quad (1)$$

$$mpe = nF \cdot \frac{\Delta m}{Q} = -nC_f F \frac{\Delta f}{Q} \quad (2)$$

where  $\Delta m$  is the mass change,  $\Delta f$  is the change in resonance frequency,  $f_0$  is the fundamental resonance frequency (7.995 MHz),  $A$  is the surface area of the electrode (0.196 cm<sup>2</sup>),  $\mu_q$  is the shear modulus of quartz (2.947\*10<sup>11</sup> g·cm<sup>-1</sup>·s<sup>-2</sup>),  $\rho_q$  is the density of quartz (2.684 g cm<sup>-3</sup>),  $C_f$  is the sensitivity factor for this setup (1.34 ng·Hz<sup>-1</sup>),  $Q$  is the charge passed through the electrode in Coulombs,  $F$  is the Faraday constant (96485 C mol<sup>-1</sup>), and  $n$  is the valence number of the ion.

However, the Sauerbrey equation always needs a correction related to the electrode/electrolyte interface. Another factor that affects the frequency shift is the change of density ( $\rho_L$ ) and viscosity ( $\eta_L$ ) of the electrolyte in contact with the quartz crystal electrode,<sup>16,26</sup> as follows

$$\Delta f_{\eta\rho} = -f_0^{\frac{3}{2}} \left[ \frac{\Delta(\eta_L \rho_L)}{\pi \mu_q \rho_q} \right]^{\frac{1}{2}} \quad (3)$$

The observed frequency change  $\Delta f$  is the sum of the frequency change associated with mass loss/gain ( $\Delta f_m$ ) and the change in ( $\eta_L \rho_L$ ) during the electrochemical process:

$$\Delta f = \Delta f_m + \Delta f_{\eta\rho} \quad (4)$$

$\Delta(\eta_L \rho_L)$  can be estimated from the change in the resistance of the quartz crystal ( $\Delta R$ ),

$$\Delta R = [2\pi f_0 \Delta(\eta_L \rho_L)]^{1/2} A/k^2 = -[\pi(2 \mu_q \rho_q)^{\frac{1}{2}} A/(k^2 f_0)] \Delta f_{\eta\rho} \quad (5)$$

where  $k$  is an electromechanical factor. From eq 5, we see that  $\Delta f_{\eta\rho}$  has a negative linear correlation with  $\Delta R$ . However, due to the inhomogeneous concentration of electrolyte near

electrode during charge-discharge process (including density and viscosity,  $\eta_L\rho_L$ ), and the  $\Delta R$  is also affected by roughness of electrode, which changes when strong deposition reaction occurs, such as electrolyte decomposition at  $< 2.6$  V region.<sup>26</sup> It is difficult to make an accurate quantitatively relationship between  $\Delta R$  and  $\Delta f_{\eta\rho}$ . In this work, we used  $\Delta R$  to do a qualitative correction of obtained  $\Delta f$  from tests. An increase of  $\Delta R$  means a decrease of  $\Delta f_{\eta\rho}$ .

### 2.3. Electrochemical Measurements

CR2025-type coin cells were used to measure the electrochemical performance. A mixture of the synthesized material, polyvinylidenedifluoride (PVDF) binder and acetylene black at a weight ratio of 8: 1: 1 soaked in N-methyl-2-pyrrolidone (NMP) solvent was coated on a 16 mm diameter Al foil current collector to prepare the electrode. The electrodes were dried at 100 °C for 12 h in vacuum before each test. The weight of active material in each electrode was kept at  $1.25 \pm 0.1$  mg  $\text{cm}^{-2}$ . An argon-filled glove box was used to assemble the CR2025-type coin cells. Lithium foils and Celgard 2400 film were used as counter electrode and separator, respectively. 1 M  $\text{LiPF}_6/\text{EC}/\text{DMC}$  (EC: DMC = 1:1 v/v,  $\text{H}_2\text{O}$  concentration  $< 5$  ppm) was used as the electrolyte. A Land-V34 battery tester (Wuhan, China) was used for galvanostatic control of the cells, which were kept at 30 °C. The current density of 1 C equals to 200  $\text{mA g}^{-1}$ . Capacities were calculated based on the weight of active material. A CHI660E work station was used to do cyclic voltammetry test. All the materials were tested between 2.0 and 4.8 V (vs.  $\text{Li}/\text{Li}^+$ ) at a scan rate of 0.2  $\text{mV s}^{-1}$ .

Electrochemical impedance spectroscopy (EIS) was performed on a VSP multichannel potentiostatic-galvanostatic system (VERSASTATV3, USA). The electrode potential was increased

stepwise from open circuit voltage (OCP) to 4.8 V and then decreased to 2.0 V with 0.1-0.2 V potentiostatic steps. Before EIS tests at each potential, the voltage was kept constant for 20 mins. The impedance spectra were recorded by applying an AC voltage of 5 mV in the frequency range from 1 MHz to 5 mHz.

### 3. Results and Discussion

#### 3.1 Microstructure, crystal structure and electrochemical performance

Fig 2a-c shows SEM images of  $\text{Li}_2\text{MnO}_3$ ,  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  and  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ . All the samples have similar microstructures, but the particle sizes are different. The  $\text{Li}_2\text{MnO}_3$  and  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  particles were between 100 and 200 nm, while those of  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  ranged from 200 and 300 nm. XRD profiles are displayed in Figure 2d. All of these three samples have distinct features indicating a layered structure. For  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  and  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$ , the strong peaks at  $18.7^\circ$  and  $44.6^\circ$  can be indexed to (003) and (104) planes of the  $\alpha\text{-NaFeO}_2$  parent hexagonal structure ( $R\bar{3}m$  symmetry).  $\text{Li}_2\text{MnO}_3$  exhibits monoclinic structure with strong peaks at  $18.6^\circ$  and  $44.7^\circ$ , which correspond to (001) and (131) planes of space group  $C2/m$ .<sup>9</sup> Both  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  and  $\text{Li}_2\text{MnO}_3$  have a broad superlattice (110) peak at  $20\text{-}25^\circ$ , which indicates cation ordering in the transition-metal layer and stacking faults formed during materials preparing process.<sup>9</sup> Fig S2 shows the refinement XRD patterns of  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ . The calculated ratio of  $\text{Li}_2\text{MnO}_3$  and  $\text{LiMO}_2$  ( $M = \text{Ni, Co, Mn}$ ) is 48.9:51.1, which is very close to 50:50. Considering the calculation error, it is acceptable to denote Li-rich material as  $0.5\text{Li}_2\text{MnO}_3 \cdot 0.5\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$ . More detailed structure information of  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  can be seen in our previous study.<sup>16</sup>

Fig 2e displays the initial charge-discharge profiles of  $\text{Li}_2\text{MnO}_3$ ,  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  and  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  at 0.1 C. For  $\text{Li}_2\text{MnO}_3$ , only a voltage plateau above 4.4 V is observed during charge.<sup>10</sup> Instead of a very stable plateau at ~4.5 V, the inclined plateau is attributed to the low conductivity of pure  $\text{Li}_2\text{MnO}_3$ .<sup>10,28</sup> During discharge, the voltage declines rapidly, showing a capacity of only 126.8 mAh g<sup>-1</sup>. The irreversible capacity ratio (ICR), defined as irreversible capacity divided by charge capacity, was 48.85%. During charge,  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  has a voltage plateau above 3.7 V, corresponding to  $\text{Ni}^{2+}/\text{Ni}^{4+}$  and  $\text{Co}^{3+}/\text{Co}^{4+}$  redox couples. It has a discharge capacity of 178.7 mAh g<sup>-1</sup> and an 18.92% ICR.  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  has a capacity of 120 mAh g<sup>-1</sup> during the initial charge process, which is associated with the  $\text{Ni}^{2+}/\text{Ni}^{4+}$  and  $\text{Co}^{3+}/\text{Co}^{3.6+}$  redox couples.<sup>9,17</sup> The plateau above 4.4 V corresponding to  $\text{Li}_2\text{MnO}_3$  activation is observed and provides an additional capacity of 200 mAh g<sup>-1</sup>. Upon discharging,  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  exhibits a sloping voltage curve and has a capacity of 244.7 mAh g<sup>-1</sup> with 22.56% ICR. The discharge capacity of  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  is much higher than the average of  $\text{Li}_2\text{MnO}_3$  and  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$ , indicating a synergistic effect between  $\text{Li}_2\text{MnO}_3$  and the layered structure in Li-rich oxide material. Lim et al. has proved that layered  $\text{LiNi}_{1/3}\text{Co}_{1/3}\text{Mn}_{1/3}\text{O}_2$  benefits from the structural stability of  $\text{Li}_2\text{MnO}_3$ .<sup>18</sup> However, the explanation for why extra capacity results from the introduction of  $\text{Li}_2\text{MnO}_3$  into layered  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  is unclear.

The CV profiles (for the first cycle) of  $\text{Li}_2\text{MnO}_3$ ,  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  and  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  are shown in Fig 2f. For  $\text{Li}_2\text{MnO}_3$ , no anodic peak emerges until ~4.4 V. The current peak between 4.4 and 4.8 V is attributed to  $\text{Li}_2\text{MnO}_3$  activation and simultaneous lithium extraction. A small reductive current peak can be observed below 3.6 V

1 corresponding to  $\text{Mn}^{4+}/\text{Mn}^{3+}$  reduction. The anodic and cathodic current densities of  $\text{Li}_2\text{MnO}_3$   
2 are distinctly smaller than those of  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  and  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ . For  
3  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$ , the first peak between 3.65 V and 4.3 V during charge corresponds to  
4  $\text{Ni}^{2+}/\text{Ni}^{4+}$  and  $\text{Co}^{3+}/\text{Co}^{3.6+}$  redox couples. The second smaller peak at  $\sim 4.5$  V is due to the  
5  $\text{Co}^{3.6+}/\text{Co}^{4+}$  redox couple.<sup>17</sup> A reduction peak centered at  $\sim 3.7$  V is observed, which is  
6 attributed to  $\text{Ni}^{4+}/\text{Ni}^{2+}$  and  $\text{Co}^{4+}/\text{Co}^{3+}$  redox couples. Below 3.0 V, no peak is observed, which  
7 indicates no  $\text{Mn}^{3+}$  formation. The CV profile of  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  shows anodic peaks  
8 between 3.65 V and 4.4 V for the  $\text{Ni}^{2+}/\text{Ni}^{4+}$  and  $\text{Co}^{3+}/\text{Co}^{3.6+}$  redox couples.<sup>17</sup> The subsequent  
9 oxidation peak from 4.4 to 4.8 V is due to  $\text{Li}_2\text{MnO}_3$  activation and lithium extraction, which  
10 is similar to that of  $\text{Li}_2\text{MnO}_3$ . During reduction, the  $\text{Ni}^{4+}/\text{Ni}^{2+}$  and  $\text{Co}^{4+}/\text{Co}^{3+}$  redox peaks at  
11  $\sim 3.8$  V resembles  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$ .<sup>5</sup>

### 13 **3.2 First-cycle interfacial properties**

14 Fig 3a displays the first cycle CV curve and the simultaneous EQCM response of  
15  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ . The corresponding  $\Delta f - \Delta Q$  (charge) plots are shown in Fig 3b and c.  
16 To help interpret these observations, analogous data pure  $\text{LiPF}_6/\text{EC}+\text{DMC}$ , without loaded  
17 materials are depicted in Fig S3.

18 The diagrams of  $\Delta R$  versus  $E$  (electrode potential) of pure  $\text{LiPF}_6/\text{EC}+\text{DMC}$  electrolyte,  
19  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ ,  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  and  $\text{Li}_2\text{MnO}_3$  during first CV cycle are shown  
20 in Fig S4.

21 In many regions, the variation of  $\Delta R$  is negligible ( $\sim 0$ ), so the Sauerbrey equation is still  
22 valid, which is similar to Tsai's and Wu's reports.<sup>14,20</sup> For example, in the 4.4-4.65 V region

during the first anodic scanning of  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ ,  $\text{Li}_2\text{MnO}_3$  activation occurs and the variation of  $\Delta R$  is near to zero. In many other regions, the variation of  $\Delta R$  is not so obvious, so the mass loss/gain is the main process affecting the shift in frequency ( $\Delta f$ ). In this study, we first calculated the mass changes and  $mpe$  values by the Sauerbrey equation, and then we analyzed and adjusted the  $mpe$  values with  $\Delta R$ . The obtained values of these parameters are listed in Table 1.

Fig 2e and Fig 3a illustrate that the capacity, current and  $\Delta f$  are all very small between open circuit potential (OCP) and 3.7 V during the first charge. Changes in this region are attributed mainly to absorption/desorption of electrolyte molecules or ions.<sup>27</sup> In the first charge,  $\Delta R$  is almost zero when the potential is below 4.65 V, which suggests the Sauerbrey equation is valid in this region. It is observed that the measured  $mpe$  is close to  $7 \text{ g mol}^{-1}$  (which is the atomic weight of Li) in the 4.2-4.4 V region, which indicates delithiation of  $\text{Li}^+$  along with  $\text{Ni}^{2+}/\text{Ni}^{4+}$  and  $\text{Co}^{3+}/\text{Co}^{3.6+}$  oxidation reactions.<sup>19</sup> However, the  $mpe$  values in 3.7-4.2 V and 4.4-4.65 V are higher than  $7 \text{ g mol}^{-1}$ , indicating additional processes. For analyzing the formation/dissolution of CEI,  $\Delta R_{\text{CEI}}-E$  plots at different potential during the first charge are displayed as a red line in Fig 3d. The corresponding Nyquist plots are shown in Fig S5a-d. The equivalent circuit, shown as an insert in Fig3d, was applied to analyze the EIS data. In this equivalent circuit,  $R_s$  represents the internal resistance of the battery,  $R_{\text{CEI}}$  and  $C_{\text{CEI}}$  represent the resistance and capacitance of the CEI film, while  $R_{\text{ct}}$  and  $C_{\text{dl}}$  represent the charge-transfer resistance and double-layer capacitance.  $W$  is the Warburg impedance related to  $\text{Li}^+$  diffusion.<sup>21</sup> The fitted impedance parameters are listed in Table S1. There is always native surface film on most cathode surfaces ( $\text{Li}_2\text{CO}_3$  on lithium transition metal

1 oxides).<sup>22</sup> This is the source of  $R_{\text{CEI}}$  in the initial state. It can be seen that the  $R_{\text{CEI}}$  decreases  
 2 with the potential increases in 3.7-4.2 V region, which indicates the dissolution of CEI layer.  
 3 There is always HF in electrolyte. Native  $\text{Li}_2\text{CO}_3$  can react with HF and lead to dissolution.<sup>24</sup>  
 4 Electrochemical decomposition of  $\text{Li}_2\text{CO}_3$  was also reported by previous study.<sup>27</sup> So the  
 5  $\text{Li}_2\text{CO}_3$  degradation is a possible pathway of CEI dissolution, which can make the measured  
 6 *mpe* value higher. This is consistent with the high *mpe* value in 3.7-4.2 V region. In the  
 7 4.4-4.65 V region,  $R_{\text{CEI}}$  increases slightly, indicating new CEI film produced. So the mass  
 8 change is attributed to the irreversible decomposition of the  $\text{Li}_2\text{MnO}_3$  component in  
 9  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  and to CEI formation. Fig S3 further confirms the above analysis.  
 10 The decreased  $\Delta f$  during charge indicates no gold base dissolution (increased  $\Delta f$ ), which  
 11 means gold is stable in  $\text{LiPF}_6/\text{EC}+\text{DMC}$  electrolyte. The  $\Delta f$  vary is originated from  
 12 electrolyte reactions. For pure  $\text{LiPF}_6/\text{EC}+\text{DMC}$  electrolyte, the absorption/desorption process  
 13 of electrolyte molecules/ions occurs in the OCP-4 V region. In the 4-4.65 V region, it can be  
 14 observed from CV curve that electrolyte begins to oxidize. Frequency decrease and negligible  
 15  $\Delta R$  can also be seen, corresponding to a mass increase and indicating the CEI layer derived  
 16 from electrolyte formed. CEI formation can reduce the calculated *mpe* value. In 3.7-4.2 V  
 17 region of  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ , native CEI layer dissolved. But the *mpe* value in the 4-4.2  
 18 V region is smaller than that in 3.7-4 V, which is attributed to new CEI film formation  
 19 derived from electrolyte. Between 4.2 and 4.4 V, the *mpe* value is slightly smaller than 7 g  
 20  $\text{mol}^{-1}$ , which is also attributed to new CEI formation. In the 4.4 V-4.65 V region, the mass  
 21 change is attributed to the irreversible decomposition of  $\text{Li}_2\text{MnO}_3$  component in  
 22  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  and to CEI formation.

There have been many studies about the decomposition of  $\text{Li}_2\text{MnO}_3$ , and  $\text{O}_2^{2-}$  (true species or localized electron holes on oxygen).  $\text{Li}_2\text{O}$  were proved to be formed in different research.<sup>6-10</sup> The specific reactions may follow as eq 6 and eq 7.

For eq 6, two electrons are transferred and four  $\text{Li}^+$  ions are extracted. The *mpe* value of eq 6 is  $28/2 = 14 \text{ g mol}^{-1}$  and  $\text{Li}^+$  extraction can lead to mass loss. For eq 7, no electrons are transferred and no species are lost from the material, so the mass change of eq 7 is zero. As can be seen in Table 4, the maximum of mass loss of  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  in 4.4-4.65 V region is 277.4 ng when eq 6 is the only reaction. However, the real mass loss is 137.5 ng, which is 49.57% of the maximal mass loss originating from  $\text{Li}_2\text{MnO}_3$  activation. Considering that CEI film formation leads to mass gain, and chemical decomposition according to eq 7 does not affect the mass, electrochemical decomposition according to eq 6 is the main process of  $\text{Li}_2\text{MnO}_3$  activation for Li-rich oxide  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ . The measured *mpe* value in 4.4-4.65 V region is  $12.85 \text{ g mol}^{-1}$ , which is slightly smaller than 14 for eq 6. CEI film formation leads to a mass gain for the electrode, but no electrons transfer of electrode material, and makes the measured *mpe* value smaller, which is consistent with our experiment. In the region above 4.65 V, the  $\Delta R$  is slightly increased, and a further oxidation reaction of electrolyte occurs because of the high charge voltage.

Fig 3c illustrates the  $\Delta f - \Delta Q$  plot during the first discharge process, and the corresponding mass change and *mpe* values are listed in Table 1.  $\Delta R$  increases during the first discharge, which leads to a negative shift of frequency. So the actual shift of frequency

1 caused by the mass gain is smaller than that observed in Fig 2c, and the real *mpe* value is  
 2 smaller than that listed in Table 1. In the 4.8-4.1 V region, a continuous oxidation reaction of  
 3 electrolyte occurs. In the region below 2.6 V, a decomposition reaction of electrolyte occurs,  
 4 which is consistent with the very small capacity in the charge-discharge curve, as  
 5 demonstrated in Fig 2e. Considering the previous reports and our experimental data (*mpe* =  
 6 53.42,  $\Delta R$  increase),  $\text{Li}_2\text{CO}_3$  (*mpe* =37) is one of the possible product.<sup>10,28</sup> In these two  
 7 regions, there are no valence state changes for the metal ions in  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ , and  
 8 the interfacial reactions for  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  and pure electrolyte are very similar. In  
 9 the 4.1-2.6 V region, the insertion of  $\text{Li}^+$  causes the mass to increase. However, the *mpe* value  
 10 in the 4.1-2.6 V region is higher than  $7 \text{ g mol}^{-1}$ , indicating that the insertion of  $\text{Li}^+$  maybe not  
 11 be the only electrochemical process. But considering the shift of frequency caused by  $\Delta R$ ,  
 12 more proof should be given. The blue line in Fig 3d displays the  $\Delta R_{\text{CEI}}$ -E plot of  
 13  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  at different potentials during the first discharge. The corresponding  
 14 Nyquist plots are shown in Fig S5e-f, and the fitted impedance parameters are listed in Table  
 15 S2. It is observed that  $R_{\text{CEI}}$  increases as the potential decreases in the 4.1-2.6 V region.  
 16 Considering that the *mpe* value is greater than  $7 \text{ g mol}^{-1}$ , a new CEI film with lower  
 17 conductivity has apparently formed in this region. For pure  $\text{LiPF}_6/\text{EC}+\text{DMC}$  electrolyte, the  
 18 frequency change is slightly higher in the 4.1-2.6 V region. Considering that an increase in  
 19  $\Delta R$  leads to negative shift of frequency, the measured frequency increase implies CEI  
 20 dissolution and mass loss. The difference between pure electrolyte and  
 21  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  is attributed to the valence state changes of metal ions in this region,

1 since the interfacial reactions are very similar when there are no valence state changes of  
2 metal ions in the region above 4.1 V and below 2.6 V.

3 To further clarify the interfacial property of Li-rich  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  material,  
4 the interfacial properties of layered  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  and pure  $\text{Li}_2\text{MnO}_3$  were also  
5 investigated for comparison. As demonstrated in Fig 4a, the CV curve during the first cycle  
6 and the simultaneous EQCM response of  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  can be observed. The  
7 corresponding  $\Delta f$ - $\Delta Q$  plots are shown in Fig 4c and 4e. Table 2 summarizes the mass change  
8 and *mpe* values during first cycle. As with  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ , electrolyte  
9 absorption/desorption occurs below 3.65 V. The *mpe* value in the 3.65-3.9 V region is near 7  
10  $\text{g mol}^{-1}$  and  $\Delta R$  is insignificant, which indicates delithiation along with  $\text{Ni}^{2+}/\text{Ni}^{4+}$  and  $\text{Co}^{3+}/$   
11  $\text{Co}^{3.6+}$  oxidation. In the 3.9-4.4 V region,  $\Delta R$  increases slightly, while the *mpe* value varies.  
12 The large *mpe* values indicate that dissolution of the native CEI layer is the dominated  
13 process, as with  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ . When the potential is above 4.4 V, the variation of  
14  $\Delta R$  is near to zero and the Sauerbrey equation is applicable. In the 4.4-4.53 V region,  $\text{Co}^{3.6+}/$   
15  $\text{Co}^{4+}$  oxidation reactions occur along delithiation.<sup>17</sup> The *mpe* value in the 4.4-4.53 V region is  
16  $6.73 \text{ g mol}^{-1}$ , which is slightly smaller than  $7 \text{ g mol}^{-1}$ . This result demonstrates that  $\text{Li}^+$   
17 extraction along with  $\text{Co}^{3.6+}/\text{Co}^{4+}$  oxidation are the main processes in this region. Nyquist  
18 plots of  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  shown in Fig S6 also illustrate that  $R_{\text{CEI}}$  is slightly increased,  
19 indicating that there is new CEI film formed. When the voltage is higher than 4.65 V,  
20 electrolyte oxidation occurs. For the first discharge of  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$ , it is very similar  
21 to that of Li-rich  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ .  $\Delta R$  increases during first discharge, as with  
22  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ . Continuous electrolyte oxidation occurs in the 4.8-4.1 V region and

electrolyte is decomposed when the potential is below 2.6 V. Between 4.1 and 2.6 V,  $\text{Li}^+$  insertion is accompanied by metal ion reduction and CEI film formation.

Fig 4b shows the CV curve for the first cycle and the simultaneous EQCM response of  $\text{Li}_2\text{MnO}_3$ . The corresponding  $\Delta f - \Delta Q$  (charge) plots are displayed in Fig 4d and f. Table 3 summarizes the *mpe* value during first cycle. For the  $\text{Li}_2\text{MnO}_3$  electrode,  $\Delta R$  increases when the voltage is below 3.8 V but hardly varies when the potential is above 3.8 V. There is no obvious electrochemical reaction besides the absorption/desorption of electrolyte molecule/ion when the potential is below 3.8 V. In the 3.8-4.05 V region, the native CEI film dissolves, as with the case of Li-rich material. In the region between 4.05 and 4.4 V, new CEI is produced. In the 4.4-4.65 V region, the Sauerbrey equation is valid and the decomposition of  $\text{Li}_2\text{MnO}_3$  is the dominant reaction. As displayed in Table 4, the mass of loaded  $\text{Li}_2\text{MnO}_3$  is 4.777  $\mu\text{g}$ . The maximum extracted  $\text{Li}^+$  is 567.589 ng when eq 6 is the only decomposition pathway. However, the real mass loss of  $\text{Li}_2\text{MnO}_3$  is only 7.959 ng, only 1.4% of the maximal mass loss from  $\text{Li}_2\text{MnO}_3$  activation and much smaller than 49.57% of Li-rich oxide. The *mpe* value is 1.51  $\text{g mol}^{-1}$ , which is distinctly smaller than the 14  $\text{g mol}^{-1}$  of eq 6. This result indicates that CEI film formed. Considering that the new CEI film formation can counter some of the mass loss, we conclude that a chemical decomposition of  $\text{Li}_2\text{MnO}_3$  to  $\text{Li}_2\text{O}$  and  $\text{MnO}_2$  is the dominant reaction, as shown in eq 7, which coincides with the electrochemical results in Fig 2f.

However, electrochemical decomposition is the main process of  $\text{Li}_2\text{MnO}_3$  component in Li-rich oxide  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$ . The obviously different routes of  $\text{Li}_2\text{MnO}_3$  decomposition reactions in the same potential region demonstrates that there is a synergistic effect between  $\text{Li}_2\text{MnO}_3$  ( $C2/m$ ) and the layered structure ( $R\bar{3}m$ ) in Li-rich oxide material,

1 which is in accordance with the first charge-discharge profiles in Fig 2e. Pure chemical  
2 decomposition does not contribute to capacity. So the different decomposition pathway of  
3  $\text{Li}_2\text{MnO}_3$  in Li-rich oxides is the reason why Li-rich oxides can provide higher capacity than  
4 pure  $\text{Li}_2\text{MnO}_3$  and  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  materials.

5 The first discharge of pure  $\text{Li}_2\text{MnO}_3$  is also very similar to that of Li-rich oxide, where  
6 electrolyte oxidation occurs in the 4.8-3.9 V region and electrolyte is decomposed for  
7 potentials below 2.6 V. In the region between 3.9 and 2.6 V,  $\text{Li}^+$  inserts into the electrode and  
8 CEI is formed. But there is some difference. The *mpe* value is much smaller than that of  
9  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  and  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$ , indicating that changes in the valence state  
10 of  $\text{Ni}^{4+}$  and  $\text{Co}^{4+}$  have a bigger effect on CEI formation than those of  $\text{Mn}^{4+}$  and  $\text{O}_2^{2-}$ .

11 Scheme 1a demonstrates the EQCM working principle in this work. The  $\text{Li}^+$   
12 insertion/extraction and SEI evolution occurring on the electrodes lead to mass change, which  
13 can be measured by the frequency change of crystal quartz. The CV curves can also be  
14 recorded, which can be used to calculate the charge evolution during the test. Combining the  
15 mass change and charge evolution, we can get the *mpe* value, which is closely related with  
16 different kinds of reactions and important to determine what reactions occur in different  
17 potential region, such as  $\text{Li}_2\text{MnO}_3$  activation in 4.4-4.65 V region during first charge. Scheme  
18 1b illustrates the proposed interfacial reaction mechanism of Li-rich oxides during the first  
19 charge, based on the previous results in this article. Solvated electrolyte ions adsorb on the  
20 surface of the electrode in the initial period. Subsequently,  $\text{Li}^+$  extracts from material. When  
21 the potential is below 4.4 V,  $\text{Ni}^{2+}$  is oxidized to  $\text{Ni}^{4+}$  to compensate for the  $\text{Li}^+$  extraction.  
22 Native CEI dissolution takes place at the same time. In the voltage region between 4.4 V and  
23 4.65 V,  $\text{Li}_2\text{MnO}_3$  activation and new CEI formation occurs. At higher potentials, electrolyte  
24 oxidation is the dominant reaction. Detailed reactions in the  $\text{Li}_2\text{MnO}_3$  activation region of  
25 Li-rich oxides and pure  $\text{Li}_2\text{MnO}_3$  are depicted in scheme 1c. For pure  $\text{Li}_2\text{MnO}_3$ , the activation

process is mainly chemical decomposition to  $\text{Li}_2\text{O}$  and  $\text{MnO}_2$ . However, for Li-rich oxides, electrochemical decomposition to  $\text{Li}^+$ ,  $\text{O}_2^{2-}$  and  $\text{MnO}_2$  is the dominant pathway. The proposed main interfacial reaction mechanism of Li-rich oxides during first discharge is illustrated in Scheme 1d. Continuous electrolyte oxidation occurs in the high voltage. After the voltage dropping to 4 V,  $\text{Li}^+$  insertion accompanied by metal ion and  $\text{O}_2^{2-}$  reduction subsequently occurs, while CEI forms in the same time. When the voltage is below 2.6 V, electrolyte decomposition is the main process.

#### 4. Conclusions

In summary, we investigated the  $\text{Li}_2\text{MnO}_3$  activation pathway and CEI formation/dissolution of  $x\text{Li}_2\text{MnO}_3 \cdot (1-x)\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  ( $x = 0, 0.5, 1$ ) cathode materials in 1 M  $\text{LiPF}_6/\text{EC}+\text{DMC}$  by in-situ EQCM and EIS. A synergistic effect between layered  $\text{Li}_2\text{MnO}_3$  and  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$  component that explains the extra-high capacity for  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  cathode was found. The synergistic effect in Li-rich  $\text{Li}_{1.2}\text{Ni}_{0.12}\text{Co}_{0.12}\text{Mn}_{0.56}\text{O}_2$  cathodes can affect the activation pathway of the  $\text{Li}_2\text{MnO}_3$  component in Li-rich material. Specifically, the activation of pure  $\text{Li}_2\text{MnO}_3$  is governed by chemical decomposition to  $\text{Li}_2\text{O}$ . However,  $\text{Li}_2\text{MnO}_3$  activation in Li-rich material is dominated by electrochemical activation to  $\text{O}_2^{2-}$  (oxygen redox). Chemical decomposition does not contribute to the electrode capacity because there is no delithiation. This explains why Li-rich materials ( $0.5\text{Li}_2\text{MnO}_3 \cdot 0.5\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$ ) have a higher capacity than the mean value of  $\text{Li}_2\text{MnO}_3$  and  $\text{LiNi}_{0.3}\text{Co}_{0.3}\text{Mn}_{0.4}\text{O}_2$ .

Besides activation of Li-rich materials, it has been observed that CEI formation/dissolution accompanies  $\text{Li}^+$  extraction/insertion. We also found that changes in the valence state of metal ions (Ni, Co, Mn) in Li-rich material can promote CEI formation. Focusing on reducing chemical

decomposition during first-cycle activation, and controlling the promotion of metal ions valence states changes should provide a route to improve the electrochemical performance of Li-rich materials.
